## Project 4 RU File System Report

### Block Usage

1. Block 0 is our superblock
2. Block 1 is the inode bitmap
3. Block 2 is the data bitmap
4. Block 3 through 66 ( $\text{Max\_INUM} / \text{Block\_Size}$ ) will store all the inodes of the file system
5. Any block after stores the data blocks
  - a. Simple test used 7 data blocks
  - b. Test\_case used 23 data blocks

### Benchmark Time (time varied based on the performance of the computer)

1. ./Simple\_test: 0.175s avg
2. ./test\_case: 0.133s avg

```
benchmark$ time ./simple_test
TEST 1: File create Success
TEST 2: File write Success
TEST 3: File close Success
TEST 4: File read Success
TEST 5: File unlink success
TEST 6: Directory create success
TEST 7: Sub-directory create success
Benchmark completed

real    0m0.175s
user    0m0.000s
sys     0m0.006s
```

```
benchmark$ time ./test_case
TEST 1: File create Success
TEST 2: File write Success
TEST 3: File close Success
TEST 4: File read Success
TEST 5: File unlink success
TEST 6: Directory create success
TEST 7: Directory remove success
TEST 8: Sub-directory create success
TEST 9: Large file write failure

real    0m0.133s
user    0m0.006s
sys     0m0.000s
```

## **Code Implementation**

Compiling and running our code is the same way as the project described. To implement this file system library we had to research about the specific structures we needed to implement and read the function descriptions carefully.

### **Bitmapping:**

`get_avail_ino()` and `get_avail_blockno()` are almost identical search methods. The key difference is that `get_avail_ino()` searches the inode indices/bitmaps and `get_avail_blockno()` searches the data block indices/bitmaps.

### **Inode Operations:**

`readi` and `writi` are two very similar methods that share the first two steps of each other's schema. The difference is that `readi` allows the caller to hold the data inside the inode while `writi` modifies it.

### **Directory Operations**

`dir_find()`, `dir_add()`, `dir_remove()` are 3 vital functions for the file system we are building. Finding directories proved to be a simple loop through the given directory's data block and find the specific file name given, if not found return -1. `Dir_add` was tricky to implement because we had to make sure we were traversing and handling each case correctly which led to plenty of debugging. `dir_remove()` uses `dir_find` as the main driver of the function and then handles the removal of the passed in directory.

### **get\_node\_by\_path():**

The `get_node_by_path` method is a key component of the filesystem as it tries to find the inode of any given path. Multiple file operations require the reference to the inode of a specific file or a directory. This method is implemented recursively.

**Files System Setup:**

Superblock is the main data structure that contains important information about the file system. Additionally two global variables `inodes_per_block` and `dirent_per_block` hold the number of inode structures that can fit in a block and the number of dirents structures that can fit in a block respectively.

**FUSE File Operations:**

The operation methods for the FUSE File systems were implemented using the steps provided for each operation in the code files.

**Difficulties encountered**

At each section we came across issues that would later be found through testing and connecting methods in a way where data is handled correctly and systematically. Issues like segmentation faults, syntax errors, and logic errors were common at first however as we polished each method after rigorous testing we picked up on patterns that were used in later sections. We once came across a “Software caused connection abort” error and handled this by going step by step in our logic to find where our software crashed. We found that `dir_add`, `remove`, and `get_node_by_path` methods were the most challenging because sometimes error messages would not help us so of course we resorted to print statements and breakpoints.
